This work was supported in part by the Advanced Research Projects Agency of the Department of Defense and was monitored by the U. S. Army Research Office-Durham under Contract No. DAHC04-72-C-0001, and by the National Science Foundation (NSF GK 2813X).

ABSTRACT

The usefulness of ILLIAC IV in solving numerical fluid dynamics problems is studied by developing a parallel algorithm for the unsteady two dimensional flow of an incompressible fluid around a circular cylinder. Two cases are studied, the symmetric case, for which an operational GLYPNIR program is included, and the asymmetric case, for which a partially completed GLYPNIR program is attached. The programming of a parallel algorithm for ILLIAC IV is more difficult than programming a comparable serial algorithm but this additional difficulty is compensated for by the greatly reduced computation time required to solve the problem.

1. INTRODUCTION

The numerical solution of a large class of fluid dynamic problems is currently impractical due to the enormous amounts of computation time needed to generate useful results on presently available serial processing computers. One approach to increasing computation speed using established hardware is to construct a computer which interprets a single instruction stream but causes arithmetic and logic operations to be performed on many sets of data simultaneously. This type of computer architecture has been given the descriptive terms "parallel processor" or "array processor".

ILLIAC IV is a new parallel processing computer designed by the University of Illinois and Burroughs Corporation for the Advanced Research Projects Agency (ARPA). ILLIAC IV interprets a single instruction stream in its central control unit (CU) and then causes operations to take place in 64 separate processing elements (PE), each PE acting on its own set of data. The hardware was constructed by Burroughs at Paoli, Pennsylvania, and installed at the Ames Research Center, Moffet Field, California. The computer was accepted by ARPA in December 1972 and is expected to be operational by June 1973. The Ames facilities are accessable to a large group of users through the ARPA network, a national network connecting many Universities, Government Laboratories, and Government Contractors.

There are several research areas where a very fast computer is currently needed in order to solve problems requiring the processing of large amounts of data. Problems in numerical fluid dynamics, studies in weather prediction, analysis of seismographic information to detect nuclear explosions, and the study of artificial intellegence all represent areas of active interest.

The project discussed in this report is directed toward the solution of numerical fluid dynamics problems. The overall objectives are:

1) to determine what difficulties may be encountered in programming a parallel processing computer and to suggest ways to minimize them,
2) to develop a parallel algorithm which will solve a problem previously solved by serial techniques and then compare the two results for ease of programming, speed of obtaining the solution, and accuracy, and, finally,
3) to draw some conclusions about the general usefulness of ILLIAC IV in solving numerical fluid dynamic problems.

Some of these objectives cannot be fully attained until ILLIAC IV is operational. This report presents the progress made toward meeting these objectives from June 1972 to February 1973. The initial section describes the ILLIAC IV architecture as it exists today. The following sections discuss the choice of a numerical fluid dynamic problem and the preparation of two algorithms to solve that problem. These sections are followed by several conclusions on the use of ILLIAC IV based on the experience gained during this project.

The project is jointly sponsored by the Department of Chemical Engineering (Dr. T. J. Hanratty) and the Center for Advanced Computation (Dr. A. Sameh).

2. THE ILLIAC IV SYSTEM

The ILLIAC IV array processor does not exist as a totally separate entity but is intimately linked with peripheralequipment which manages its activity and performs the services it requests. The user approaches

the ILLIAC IV system through the ARPA network and places a request for computing time with the TENEX managing system. TENEX in turn schedules and runs the job on the ILLIAC IV array processor and fulfills all the array's INPUT/OUTPUT (I/O) requests. A brief description of each section of the ILLIAC IV system follows. A more complete description has been prepared by S. A. Denenberg [1].

2.1 The ARPA Network

The ARPA network is designed to make available to a large number of users a wide variety of computational resources. Some of the locations attached to the network are indicated in the sketch in Figure 1. Network users have available such large computers as IBM 360's, a Burrough's B6700, and several PDP 10's and PDP 11's. Each location is served by an Interface Message Processor (IMP) which controls the flow of information over the net. At present, the net is functional, but due to local conventions at each site, much care is needed in its use. A network protocal now under development should make its use much easier.

2.2 The Ames Site

The Ames location is managed by a PDP 10 using a TENEX system as illustrated in Figure 2. Network users communicate with the TEN through a special control language. Documentation on this language is being prepared and should be available soon. The TENEX managing system controls a large disk data storage area, a UNICON laser storage device with a trillion bits of data storage and a B6700 for compiling programs for ILLIAC IV. It also manages the use of the ILLIAC IV array and handles all requests for I/O to and from the array. The TENEX managing system is being brought up slowly. At present it is capable of storing programs in its disk file

system and compiling ASK assembly language programs, but it is not able to run jobs on the ILLIAC array. Current projections are that it will be functional in April. Since all access to the ILLIAC array will be over the ARPA net and through the TENEX managing system, any use of the machine must wait until TENEX is functional.

2.3 The ILLIAC Array

The architecture of ILLIAC IV is unique, and an understanding of this architecture is very important to those who would program ILLIAC efficiently. The computer is composed of two major sections as shown in Figure 3. The central control unit (CU) and the processing elements (PE), 64 units each having an arithmetic and logic unit (ALU) and a process element memory (PEM). The instruction stream is interpreted by the CU. The CU then sends messages to the processing elements to conduct the indicated data handling and arithmetic operations. Each PE executes the same command but operates on the specific data stored in its own processing element memory. Thus, when repetitive operations are to be performed on different but similar data sets, ILLIAC may be used to greatly increase the speed of computation by operating on 64 data sets at a time. It is projected that ILLIAC will be capable of executing 200 million instructions per second.

One of the major limitations of the ILLIAC array is the small size of each PEM. The maximum capacity of each PEM is 2048 words, that is approximately a 2K memory in each processing unit. For many problems this means that the storage cannot be core contained and that time consuming exchanges of data between the array and peripheral storage units must be carried out.

ILLIAC operates with a 64 bit word allowing 48 bits of mantissa and 15 bits of exponent. This large word size will allow increased accuracy

over most machines using single precision arithmetic. Double precision arithmetic is not currently available on ILLIAC IV.

Information can be transferred from one processing element to another through the routing network. This feature is especially important when solving partial differential equations.

Detailed information on the operation of ILLIAC IV is presented in The ILLIAC IV Systems Characteristics and Programming Manual published by The Burroughs Corporation. A copy of the manual may be obtained through the Center for Advanced Computation.

2.4 Programming Languages

The unusual architecture of ILLIAC IV required the development of an entirely new type of Assembly language, one which would allow the user to fully exploit the features of this parallel machine. Assembly Language K (ASK) was developed for this purpose. Experience quickly demonstrated the need for a higher level language and in response to that need, GLYPNIR was developed. Because ASK and GLYPNIR are tied closely to the specific architecture of ILLIAC IV, it is particularly important to understand this architecture fairly well before attempting to learn either language. Also, given the current status of the literature describing GLYPNIR, it is important to have a fairly good understanding of Algol before attempting to learn GLYPNIR. The language is relatively easy to use for a programmer with a knowledge of the ILLIAC IV architecture. A GLYPNIR Manual has been prepared by Terry Layman and David Baer and information on how to obtain a copy can be obtained from CAC.

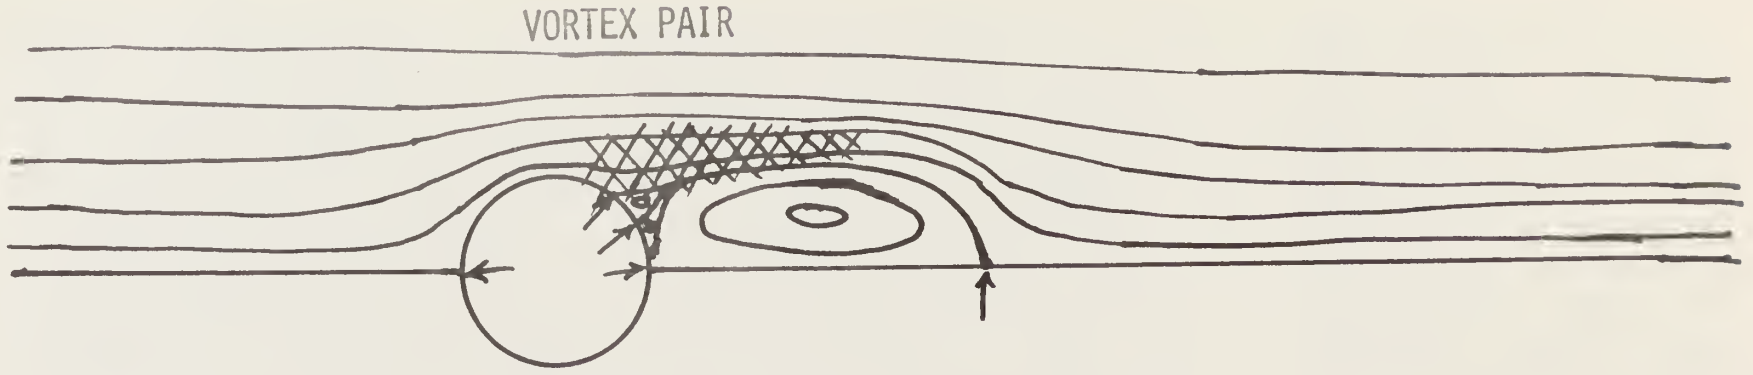
The GLYPNIR compiler produces ASK code which then must be compiled into machine language by the ASK compiler. Examination of the ASK code

produced by GLYPNIR indicates that the price paid for the convenience of a higher level language is an ASK code which is slightly inefficient. This means that computation time can sometimes be decreased significantly if often used loops in the program are coded in ASK. As a general strategy, an algorithm should be first coded in GLYPNIR. The ASK generated for internal loops should then be examined for inefficiencies. Efficient ASK code can then be substituted in the GLYPNIR program through the use of CODE statements.

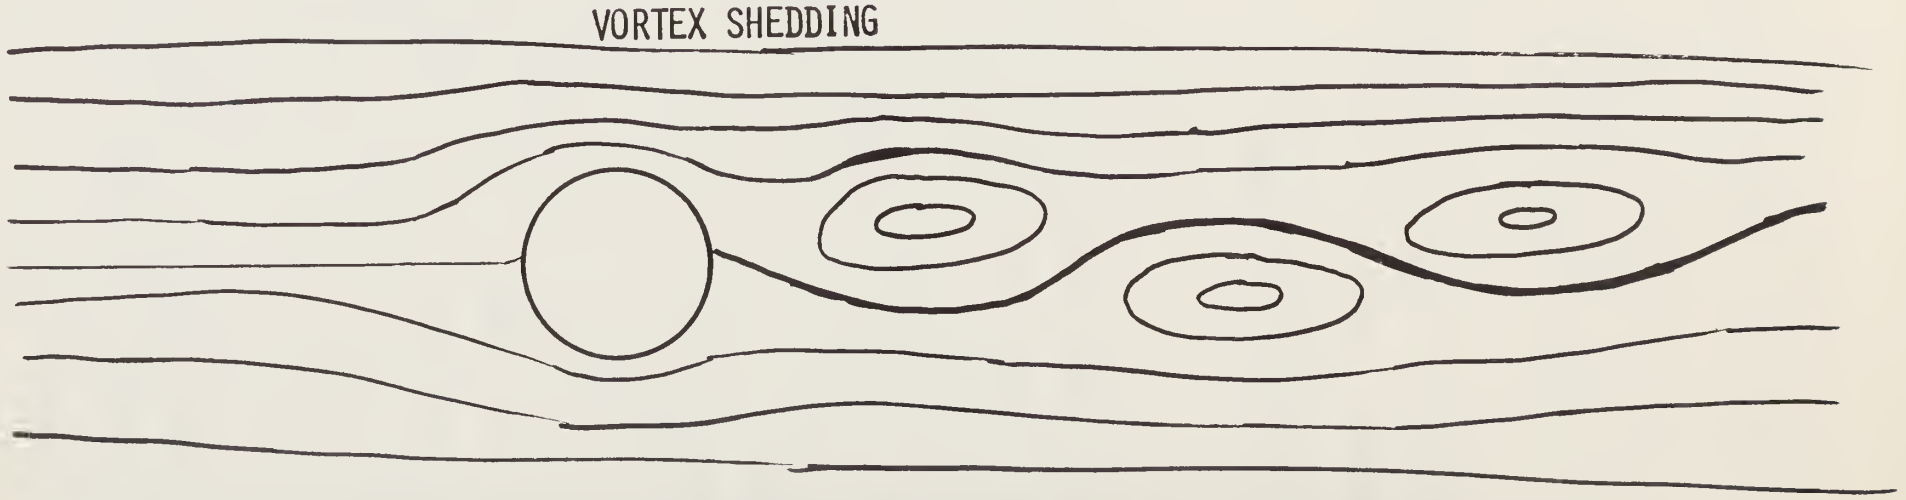
3. THE CHOICE OF A PROBLEM

One objective of this project was to develop a parallel algorithm to solve a numerical fluid dynamics problem on ILLIAC IV. There were several criteria which an appropriate problem had to meet. The problem must have been solved previously by serial techniques and the results of this solution must be available. The initial problem must be of a size and complexity which would allow it to be solved on ILLIAC IV under the uncertain conditions prevailing during the start up of a new computer. It was also desirable that the problem illustrate some interesting fluid dynamic phenomena.

The unsteady flow of an incompressible fluid around a circular cylinder was choosen as the problem to be solved. Two cases were considered, symmetric flow and asymmetric flow, and representative flow patterns for each case are illustrated in Figure 4. The symmetric flow case had been studied by J. S. Son [4] at the University of Illinois and his numerical results were on hand. This was an ideal initial problem because it could be core contained and required no special treatment of the boundary conditions. Furthermore, it was an interesting fluid dynamic problem in that it contained a growing boundary layer with separation and the formation of primary and secondary vorticies.



SYMMETRIC CASE



UNSYMMETRIC CASE

FIGURE 4

The asymmetric case had been treated by D. C. Thoman and A. A. Szewczyk [5] and the results were available in their report. This problem was more difficult requiring memory swaps and special treatment of the boundaries and, therefore, was attacked only after the symmetric algorithm was completed. However, the asymmetric case, where vortex shedding occurs, is more realistic physically when considering flows with Reynolds numbers in excess of 40.

The development of the algorithm for the symmetric case is presented in the next section. The asymmetric case is discussed in a later section.

4. THE SYMMETRIC FLOW AROUND A CYLINDER

4.1 The Problem

The unsteady two dimensional symmetric flow of an incompressible fluid around a circular cylinder was choosen as the first problem to be studied. This problem was investigated previously by J. S. Son [4] and his theoretical development and boundary conditions were adopted directly.

The governing equations were developed from the two dimensional Navier-Stokes equations. These equations were differentiated in such a way that they could be combined to eliminate the pressure terms. The resulting equation along with the continuity equation formed a pair of coupled nonlinear equations describing the fluid flow. These equations were converted to a stream function and vorticity formulation and non-dimensionalized. The independent variables were then transformed to adjust the coordinate spacing so that the boundary layer region would be adequately covered with mesh points.

The flow was assumed symmetric, thus the transverse velocity and the vorticity were assigned a value of zero along the centerline of

the flow. The fluid velocity at the outer edge of the flow field was taken to be parallel to the incoming flow and the velocity through the cylinder surface was taken as zero. The surface vorticity was estimated from the stream function distribution near the surface by expanding the vorticity function in terms of the stream function in the vicinity of the surface using the definition of vorticity. The pertinent equations developed in Son's thesis and the appropriate boundary conditions are given in Figure 5.

4.2 Development of the Algorithm

4.2.1 Introduction

The parallel algorithm developed to solve this problem was patterned after the serial algorithm used by Son. The general solution scheme is shown in Figure 6. The flow is assumed to start impulsively from rest and the initial stream function values are taken as those for the potential flow case. The finite difference form of the stream function equation is then used to adjust these values to be compatable with the boundary conditions. The initial vorticity in the flow field is assigned a value of zero. The surface vorticity at time zero is determined from the stream function distribution.

When all the initial values have been determined, dimensionless time is advanced by one increment and a finite difference form of the vorticity transport equation is used to calculate vorticities at the new time level. The stream function values are then advanced by a finite difference form of the stream function equation, using the latest values of vorticity. Two different techniques for updating the stream function were used, an iterative method and a direct method. These will be discussed in more detail in a later section.

VORTICITY TRANSPORT EQUATION

$$E^2 \frac{\partial \zeta}{\partial \tau} - \frac{\partial \psi}{\partial \eta}\frac{\partial \zeta}{\partial \xi} + \frac{\partial \psi}{\partial \xi}\frac{\partial \zeta}{\partial \eta} = \frac{2}{N_{Re}}\left[\frac{\partial^2 \zeta}{\partial \xi^2} + \frac{\partial^2 \zeta}{\partial \eta^2}\right]$$

STREAM FUNCTION EQUATION

$$E^2 \zeta = \frac{\partial^2 \psi}{\partial \xi^2} + \frac{\partial^2 \psi}{\partial \eta^2}$$

INITIAL CONDITION FOR STREAM FUNCTION

$$\psi = e^{\pi\xi}\left[1 - e^{-2\pi\xi}\right] \sin(\pi\eta)$$

BOUNDARY CONDITIONS

$\xi = 0$

$\psi = 0 \; ; \; \frac{\partial \psi}{\partial \xi} = 0$

$\zeta = E^{-2}\frac{\partial^2 \psi}{\partial \xi^2}\Big|_{\xi=0}$

$\xi \to \infty$

$\psi \to e^{\pi\xi} \sin(\pi\eta)$

$\zeta = 0$

$\eta = 0$ AND 1

$\psi = 0$

$\zeta = 0$

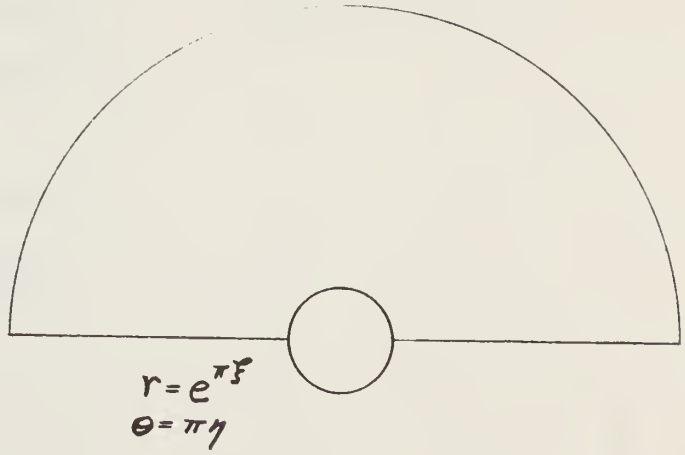


FIGURE 5

COMPUTATIONAL ALGORITHM

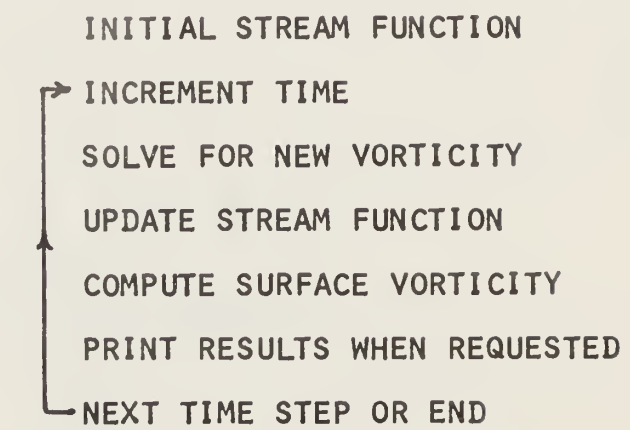

FIGURE 6

After the vorticity and stream function values have been updated in the interior of the flow region, the surface vorticity is adjusted to be compatible with the current stream function distribution near the surface. If requested, the value of all variables at this time level can be printed out at this point. The computation can then proceed by incrementing time and repeating the steps described above or it may be terminated.

The following sections treat in more detail each of the steps in the basic algorithm.

4.2.2 The initial solution

The values of the stream function at time zero were obtained from the analytic equations for the potential flow of a fluid of infinite extent about a circular cylinder. Since the fluid is assumed to be set into motion impulsively, at time zero, the boundary layer will be confined to a vanishingly thin region next to the surface of the cylinder and will not affect the rest of the flow field. Since viscous effects are confined to the boundary layer, the motion of the majority of the flow field is inviscid and the potential flow solution describes the motion well. Due to the need to deal with a boundary which is not at infinity but at some large but finite distance from the cylinder, a slight adjustment must be made in the analytic infinite extent values of the stream function. This is accomplished with the use of the finite difference form of the stream function equation as described below.

The actual surface vorticity at time zero should be infinite since, as the fluid impulsively assumes a velocity, a momentary velocity discontinuity exists at the surface. However, in order to obtain a tractable numerical solution, a large but finite vorticity is calculated from the stream function distribution.

The accuracy of the numerical solution at short times is in question due to the inability of the numerical scheme to account rigorously for the infinite surface vorticity and due to the difficulty in resolving the very thin boundary layer during these first few time steps. The effect that this initial error might cause in later calculations has not been determined but it is expected that it is confined to short times.

One method to improve the accuracy of the short time solution would be to use an analytic representation of a growing boundary layer to determine the values of the stream function and vorticity near the cylinder surface at a time when the boundary layer was still small with respect to the cylinder radius but when it was large enough to be resolved by the numerical scheme. The surface vorticity at this time would be finite.

4.2.3 The vorticity transport equation

The Alternating Direction Implicit (ADI) method was used to obtain the values of vorticity at the next time level. This method has been shown to be stable for fairly large time increments. Two steps are required to reach the next time level. The finite difference equations for each step are shown in Figure 7. During the first half time step the solution is taken to be implicit in the rows and explicit in the columns. In the next half time step the solution is implicit in the columns and explicit in the rows. This formulation results in the need to solve a tridiagonal matrix to obtain the implicit vorticity values in each row or column as the case may be. The Thomas Method represents a particularly simple method of solving these tridiagonal matricies. The solution is obtained by a series of calculations involving sequential terms in the coefficient matrix.

The full power of ILLIAC IV is realized only when all 64 PE's are active 100% of the time. Although this is seldom accomplished, maximum

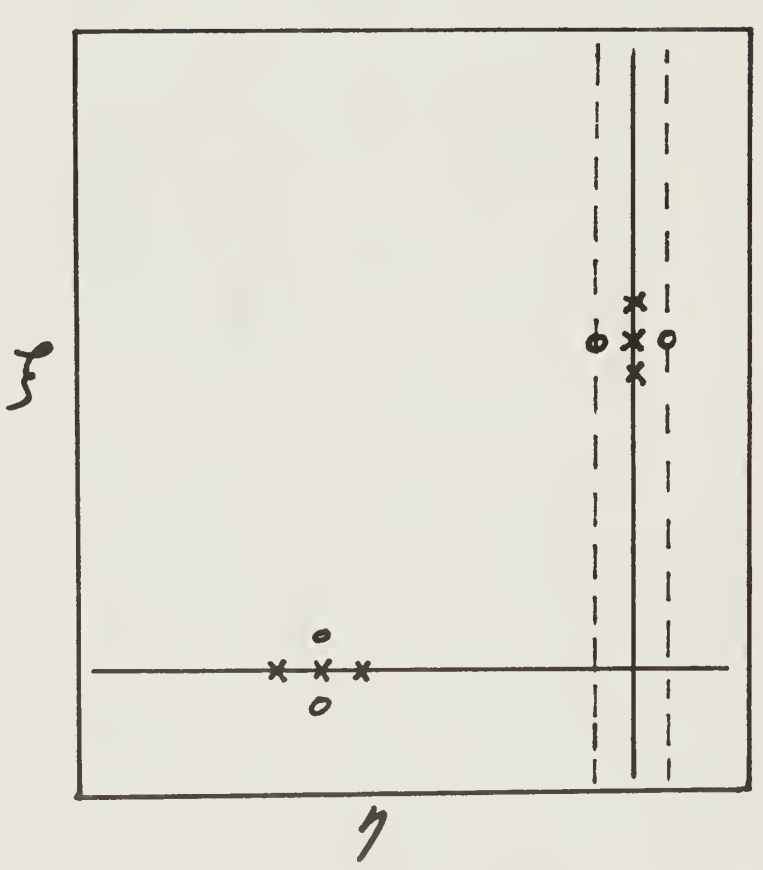
FIGURE 7

activity is a constant goal. Frequently the manner in which data is stored in PEM will determine how efficiently the computations can be carried out. For instance, solution of a tridiagonal matrix by the Thomas Method is inherently a serial process. When the solution is implicit in the columns the coefficient vectors for each column can be placed in a separate PE. Thus if the field width is choosen to be 62 (allowing two PE's for boundary conditions) then maximum use of the array processor can be obtained. The sequential processes take place as though 62 serial computers were calculating the result and thus 62 results are computed as fast as one.

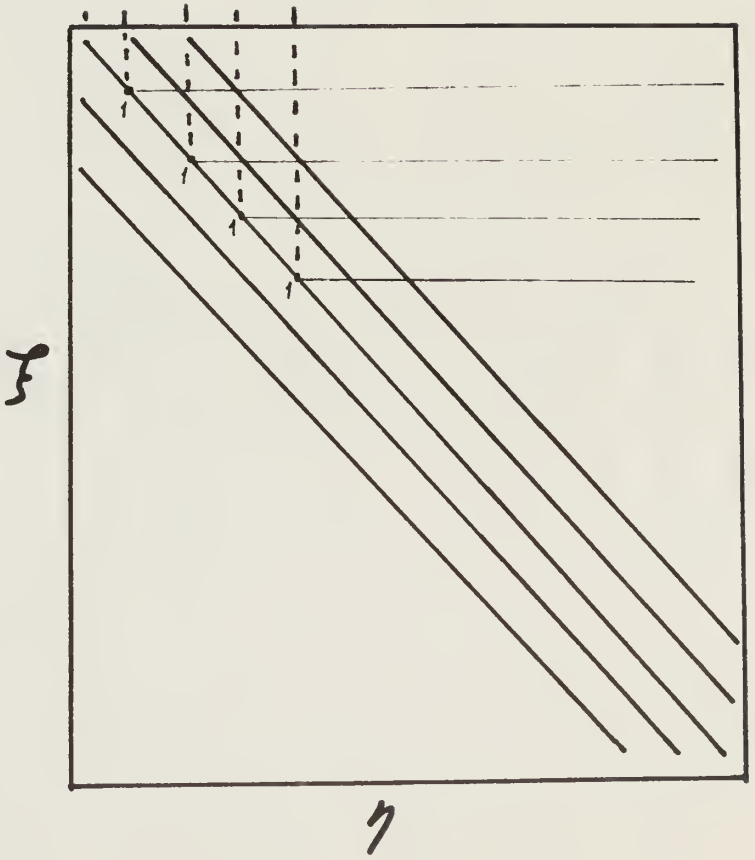
When the solution is implicit in the rows a problem arises. Since the process must follow a given sequence beginning with the first element in the row and continuing to the end of the row and then return, how can the first element of more than one row be accessed simultaneously? This problem is simply solved by shifting the coefficients in the second row one PE to the right, in the third row 2 PE's and so on until the entire field is skewed as shown in Figure 8. Then the first element in each of the 62 rows can be brought into separate PE's simultaneously. By appropriate indexing and routing of data among PE's, the solution for 62 rows is obtained simultaneously, thus using the array processor efficiently.

4.2.4 The stream function equation

Two different techniques were used to update the values of the stream function, an iterative method and a direct method. Son's algorithm used only an iterative method. Timing studies showed that updating the stream function was the most time consuming step in the algorithm and thus



DATA STORED STRAIGHT



DATA SKEWED

FIGURE 8

prompted a search for a faster method. The direct method appears to cut the computation time 50 to 60 per cent.

The iterative method used in Son's serial algorithm was the successive overrelaxation method (SOR). The computational molecule is shown in Figure 9-A and uses two updated values and two old values to determine the new center value. The serial algorithm thus starts in the lower left corner of the mesh and sweeps from left to right on each row, moving up the mesh.

In order to use ILLIAC efficiently, a whole row must be processed at once so that the 62 PE's are all active. The first scheme tried used the computational molecule in Figure 9-B. Only the point from the previous row was an updated value. Unfortunately this method did not converge.

A slightly more complicated but rapidly convergent method was developed and will be called the modified successive overrelaxation method (MSOR). This method identifies each point in the mesh as either an odd point or an even point as determined by the sum of its indicies. The method requires two passes through the mesh. On the first, each odd point is updated using only old values as shown in the left computational molecule in Figure 9-C. The second pass then updates the even points using all new information as shown in the molecule on the right. This staggering of points along with the proper index modification allows all the odd or even points in two rows to be updated simultaneously. The finite difference equation and a sketch of the computation mesh are given in figure 10-A. The MSOR method has been shown to have the same asympotic rate of convergence as the SOR method. A Center document by J. Ericksen [2] treats this in more detail. The MSOR technique makes efficient use of the ILLIAC IV array processor.

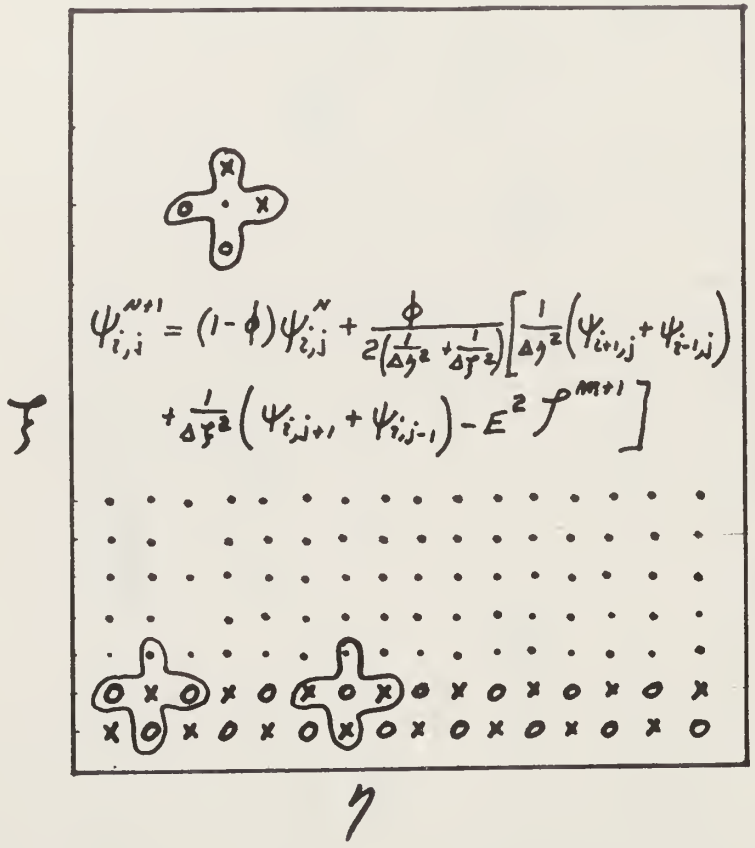
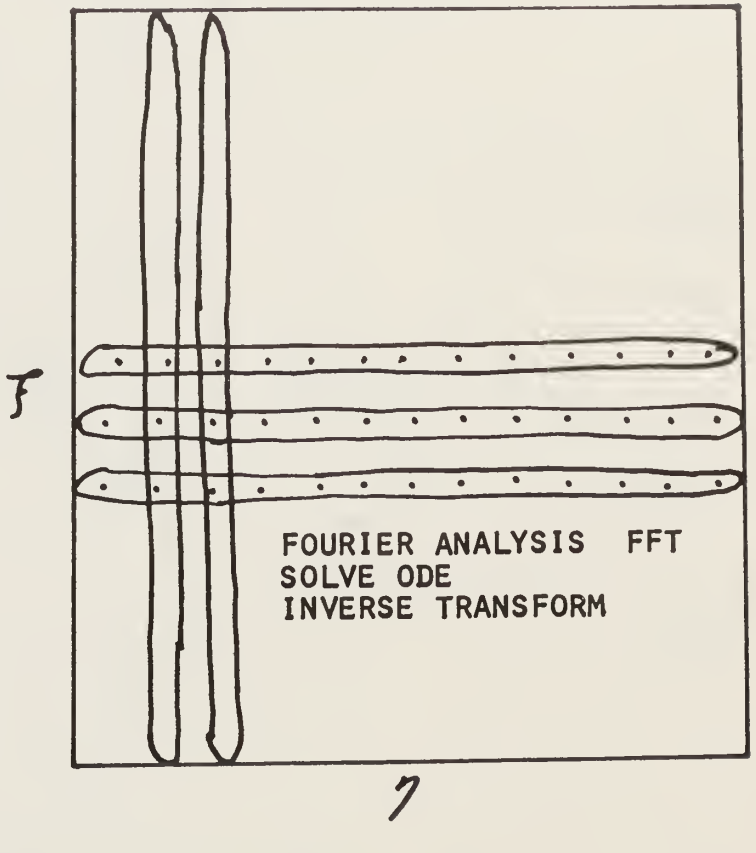
FIGURE 9

SOLUTION OF THE POISSON EQUATION



A. ITERATIVE
MSOR



B. DIRECT
HOCKNEY

FIGURE 10

The stream function equation is Poisson's Equation and its iterative solution has received much attention. Recently Hockney [3] has proposed a technique for obtaining a solution by a noniterative method with a significant savings in computation time. Since the iterative solution of Poisson's Equation represented more than 80% of the total computation time for the problem, it was decided to try Hockney's method. This direct method limits the number of mesh points in each direction to (2^n+1), where n is any integer. This is an undesirable feature but in most cases it is quite tolerable given the increased computational speed. The program was initially developed in ALGOL and then converted to GLYPNIR. The GLYPNIR program was developed by J. Ericksen and is discussed in more detail in his report [2]. The method Fourier transforms the vorticity based variables along a whole row, resulting in a series of Fourier coefficients which are independent from column to column (PE to PE) but are implicit up the columns. The computational mesh is shown in Figure 10-B. In effect the Fourier analysis has reduced the problem from one of solving a partial differential equation to one of solving a series of coupled ordinary differential equations. This later solution is accomplished by inverting a simple tridiagonal matrix. The resulting inverse Fourier components are then converted back by Fourier synthesis to yield the stream function distribution. The method reportedly uses ILLIAC efficiently and thus should represent a savings of time over the iterative method.

Test programs for each method of updating the stream function have been prepared in GLYPNIR. The iterative program is titled CICHY/GLYSOND and the direct program is called CICHY/GLYDIRECT.

4.3 Programming the Algorithm

The strategy used in programming this algorithm was to use subroutines to represent separate logical steps in the algorithm. The subroutine MAIN controls the program, calling other routines as needed. The subroutine names are descriptive of the function they perform.

The program is designed to handle up to 62 internal mesh points across the field and up to 254 internal mesh points along the field. Boundary conditions are inserted outside these points to complete the definition of the field.

The program parameters are specified in the subroutine SYSTEM PARAMETERS. They are the Reynolds Number (NREY), the dimensionless time increment (DT), the dimensionless time limit for the problem (TLMT), the error limit for the convergence of the iterative solution of the stream function equation (LIMIT), the total (includes boundary) number of mesh points in the circumferential direction (NETA), the total number of mesh points in the radial direction (NTSI), the maximum value of the circumferential coordinate (ETAMAX), the maximum value of the radial coordinate (TSIMAX), and the increment in time steps at which printouts are to be taken (PINC). Given these parameters,the program generates all the other information and control parameters it needs to solve the problem.

The two GLYPNIR programs developed are listed in Appendicies A and B. These programs contain many comments indicating how the actual operations of the algorithm are carried out in the computer.

4.4 Testing the Algorithm

GLYSOND is coded in GLYPNIR and has been successfully compiled on the GLYPNIR Compiler. The ASK produced from the compilation has been

successfully compiled into machine language. This machine language has not been tested on the ILLIAC IV. However, a simulator for the ILLIAC IV hardware has been developed and runs on a Burroughs B6700. With this simulator, machine code can be tested just as if it were running on ILLIAC IV. The major problem with testing code on the simulator is that, since the simulator runs in a serial manner, it runs much slower than ILLIAC , in fact the ratio is 200,000 to one.

It was not possible to test the machine code from GLYSOND for a reasonably sized mesh. Therefore, a 9x17 mesh was chosen and the number of iterations in the iterative MSOR was limited to six. Even so, to accomplish three time steps on the simulator required 12 minutes of CPU time.

In order to check the results of this abbreviated mesh problem it was necessary to develop a serial solution to the problem. Son's FORTRAN program was converted to an ALGOL program titled CICHY/MASTER, Appendix C. MASTER was used on a 31x51 mesh at Reynolds Number of 40 and the results checked well with those of Son. The same program was then used to generate results for 3 time steps using a 9x17 mesh and with iterations in the SOR limited to 6. These results compared well with the results from GLYSOND. This close comparison was taken as proof that the GLYPNIR program worked well and was ready to be tested on ILLIAC IV.

The same test procedure was applied to the program using the direct solution of the stream function equation. The GLYPNIR program is titled CICHY/GLYDIRECT, Appendix B, and the ALGOL program is CICHY/DIRECT, Appendix D.

In order to have numerical results to check the solution obtained from GLYDIRECT on ILLIAC IV, DIRECT was used to solve the problem on

a 33x65 node mesh. These numerical results should compare closely with the numerical results obtained from GLYDIRECT run on ILLIAC IV using a similar sized mesh if the program is operating correctly. These numerical results are currently stored with the numerical results of Son at the Department of Chemical Engineering.

The next step in testing GLYSOND and GLYDIRECT is to run them on ILLIAC IV. This should be possible at least by June 1973. GLYSOND as shown in Appendix A is set up to solve a 9x17 mesh and limit MSOR to six iterations. A copy of this program is now resident in the TENEX file system at Ames and John Gaffney and Marvin Graham will attempt to run this as soon as the ILLIAC is ready. These results should compare well with those obtained from the simulator (the printouts are stored at the Department of Chemical Engineering). The next step should be to remove cards 153 and 597 from GLYSOND which will allow MSOR to iterate to convergence. Then run GLYSOND with NREY=40, NETA=31 and NTSI=51, and compare these results with those obtained by Son. CPU time should be requested so that comparisons of running time and accuracy can be made.

After GLYSOND has been tested, GLYDIRECT should receive similar testing. Because of changes in the GLYPNIR compiler one or two variable names in GLYDIRECT may now be reserved words. The compiler will point these out and they should be changed.

At present the final I/O specification are still not complete. It is expected that they should be finished soon and that as soon as they are finished a form of GLYPNIR I/O for ILLIAC IV will be implemented.

4.5 Problems with this Symmetric Formulation

There are several features of the symmetric formulation of the problem which indicate that a more general approach is desirable.

The case of symmetric vorticies is realized in practice only up to a Reynolds number of about 40. Above this Reynolds number the flow breaks down into a pattern of vortex shedding. The symmetric formulation cannot represent this flow pattern and is thus limited in its range of application.

The use of circular cylindrical coordinates limits the extent to which the downstream boundary can be moved away from the cylinder. The parallel flow assumption made at this boundary is fairly restrictive and it is important that it have a negligible effect on the size and shape of the trailing vorticies and on the pressure distribution around the cylinder. Due to the diverging radial coordinate lines, an unreasonable number of mesh points must be added to retain adequate downstream resolution as the boundary is moved away from the cylinder.

The mesh spacing in this formulation follows a strict geometric pattern, modified slightly to better account for the boundary layer. In fact, there are regions other than the boundary layer where variable gradients may be large but which are not adequately covered with mesh points, such as the shear layer at the near edges of the vorticies. It would be desirable to be able to tailor the mesh size in any region to the size of the gradients expected in that region. This control over mesh size would require a significantly more complicated program.

4.6 Conclusions

The ability of a parallel processor to solve one particular type of numerical fluid dynamics problem has been established with the completion and testing of the GLYSOND and GLYDIRECT parallel programs. With the proper choice of the number of mesh points, these algorithms should operate efficiently and result in very rapid solutions. Actual testing on ILLIAC IV will be required to determine just how much faster the parallel program is than the serial program.

The placement of data in the PEM was shown to be very important in maintaining a high efficiency during certain portions of the program. The routing overhead required is generally negligible, except possibly in the case of very short rows.

The programming of a parallel machine is more difficult than a serial machine, but given a good understanding of the machine architecture and a working knowledge of both programming languages, the programming of an algorithm such as this one is not unreasonably difficult. Planning of data storage areas, enabling mode control, and data movement patterns represent some of the more difficult tasks.

Some of the most difficult problems encountered in the development of the symmetric algorithm related to the uncertainties in the supporting software and the unreliability of local hardware. Hopefully both of these situations have been improved to the point where they are no longer serious problems.

5. THE ASYMMETRIC FLOW AROUND A CYLINDER

5.1 Description of the Problem

The asymmetric flow around a cylinder is of particular interest since flows of this type are frequently observed in actual fluid flow situations. The famous von Karmen vortex street is an example of asymmetric vortex shedding behind a cylinder.

One objective of this second study, besides relaxing the conditions of symmetry, was to find a coordinate system which would allow the downstream boundary condition to be moved away from the cylinder while not increasing unreasonably the number of mesh points needed to maintain resolution. This constraint suggested that some kind of a rectangular coordinate system

would be appropriate downstream. However, near the surface of the cylinder, where resolution is needed for the boundary layer, a circular cylindrical coordinate system seemed best.

The search for a coordinate system which would be cylinder like near the cylinder surface and rectangular downstream led to the trial of a set of coordinates based on the potential flow solution. These conformed well to the shape of the cylinder and became rectangular at large distances from the cylinder surface. These seemingly perfect coordinates had, however, one fatal flaw, a singularity at the leading and trailing stagnation points. After considering several methods to circumvent the singularity these coordinates were abandoned in favor of the combination of circular and rectangular coordinates proposed by D. C. Thoman and A. A. Szewczyk [5].

The theoretical development used for the asymmetric problem has been taken directly from the report mentioned above. The equations to be solved are basically the same as those developed in Son's work but the boundary conditions are slightly different since the flow is asymmetric. The boundary conditions and the organization of the flow field are shown in Figure 11.

The five regions shown in Figure 11 represent areas of differing fluid activity. The mesh distribution in each region has been carefully chosen to adequately resolve the expected variable gradients.

The mesh distribution over the important parts of Regions 2 and 3 is illustrated in Figures 12 and 13. Although these drawings are not exact, they show the increased concentration of mesh points just behind the cylinder, especially in the region where a shear layer might be expected. Fewer points are placed in Region 2, upstream of the cylinder, since the flow is expected to be quite regular there.

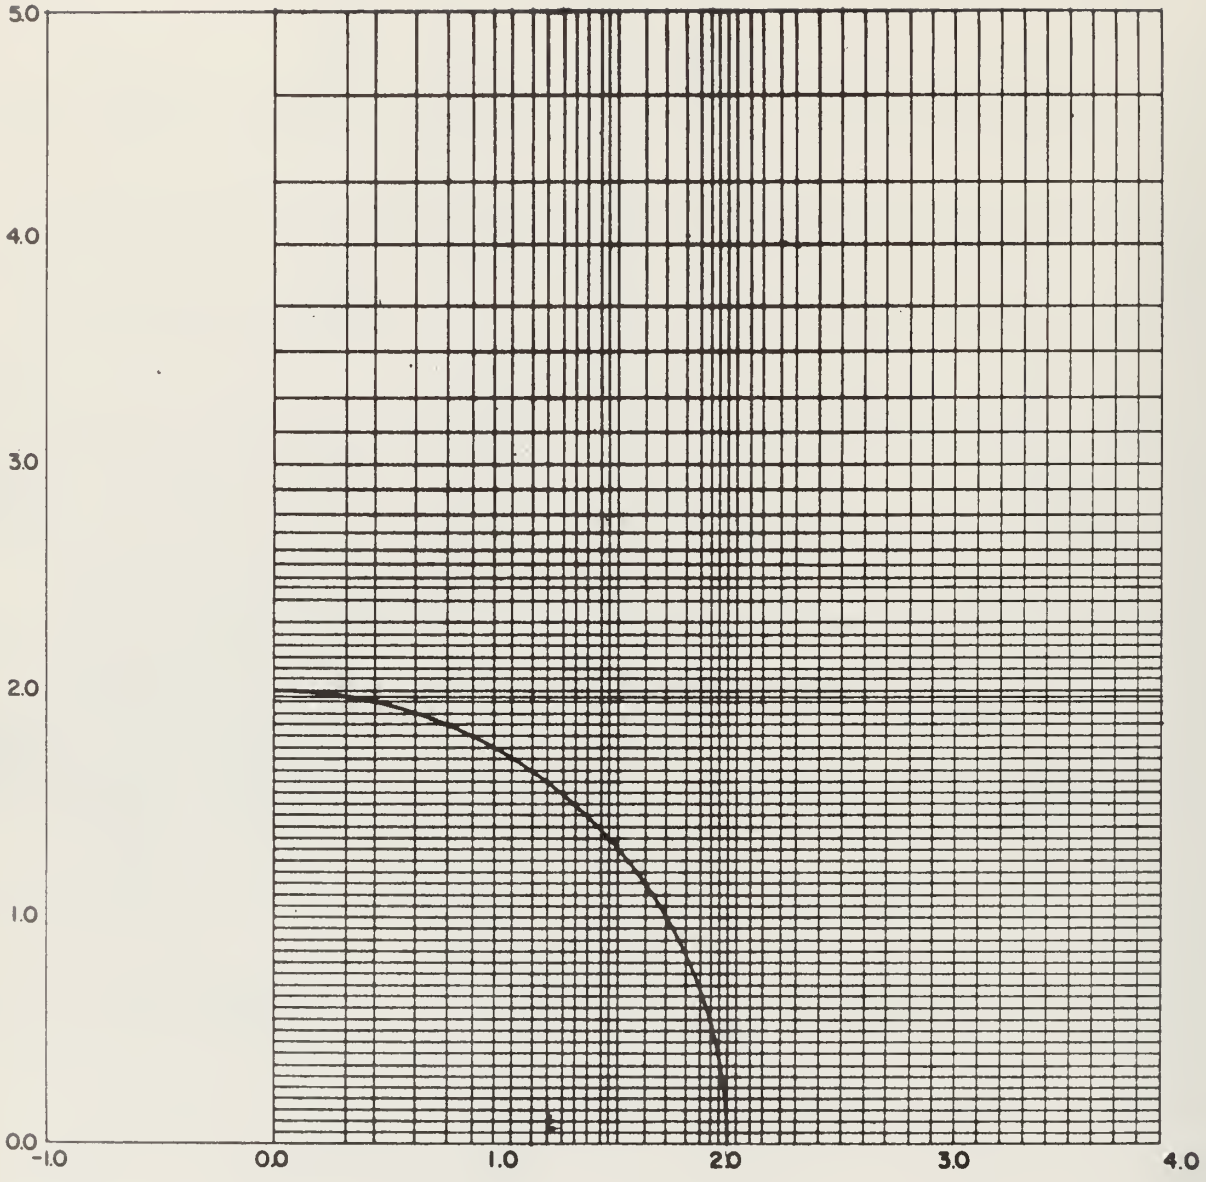
FIGURE 12



PART OF REGION 3

FIGURE 13

The relative sizes of the lateral mesh spacing used in Regions 3, 4 and 5 are shown in Figure 14. The length of Regions 4 and 5 can be changed easily to assess the effect of the downstream boundary condition on the solution.

The mesh spacings used in the cylindrical coordinates of Region 1 are illustrated in Figure 15. The points at R=2 correspond to points in the rectangular meshes of Regions 2 and 3.

5.2 Development of the Algorithm

The general algorithm for the solution of the asymmetric problem follows the same pattern as discussed for the symmetric problem. A list of the steps in the algorithm are given in Figure 16.

Two sets of finite difference equations were required, one in rectangular coordinates and the other in cylindrical coordinates. The finite difference forms of the vorticity transport equation and the stream function equation for rectangular coordinates are shown in Figure 17. The equations are explicit and allow for a variable mesh size through the inclusions of the cell width b_i and cell height a_j.

The presence of the circular coordinate system in the interior of the rectangular system excludes the use of implicit techniques. It is, therefore, necessary to devise a finite difference form of the vorticity transport equation which is explicit. This form requires that two components of the fluid velocity, u and v, be computed from the stream function distribution before the vorticity values at the next time level can be obtained. The implicit methods used to solve for the vorticity in the symmetric problem were stable for almost any reasonable time step. The stable time step for the explicit method is generally smaller, thus increasing the computation time required to obtain a given solution.

VORTICITY TRANSPORT EQUATION IN DIFFERENCE FORM

$$\frac{\zeta_{i,j}^{K+1} - \zeta_{i,j}^{K}}{\Delta\tau} + \frac{(u\zeta)_{i+1/2,j}^{K} - (u\zeta)_{i-1/2,j}^{K}}{b_i} + \frac{(v\zeta)_{i,j+1/2}^{K} - (v\zeta)_{i,j-1/2}^{K}}{a_j}$$

$$= \partial \frac{1}{b_i}\left[\frac{\zeta_{i+1,j}^{K} - \zeta_{i,j}^{K}}{0.5(b_{i+1} + b_i)} - \frac{\zeta_{i,j}^{K} - \zeta_{i-1,j}^{K}}{0.5(b_i + b_{i-1})}\right]$$

$$+ \partial \frac{1}{a_j}\left[\frac{\zeta_{i,j+1}^{K} - \zeta_{i,j}^{K}}{0.5(a_{j+1} + a_j)} - \frac{\zeta_{i,j}^{K} - \zeta_{i,j-1}^{K}}{0.5(a_j + a_{j-1})}\right]$$

STREAM FUNCTION EQUATION IN DIFFERENCE FORM

$$\psi_{i,j} = \frac{2}{d_{i,j}}\left[\frac{\zeta_{i,j}}{2} + \frac{\psi_{i-1,j}}{b_i(b_{i-1} + b_i)} + \frac{\psi_{i+1,j}}{b_i(b_i + b_{i+1})}\right.$$

$$\left. + \frac{\psi_{i,j-1}}{a_j(a_{j-1} + a_j)} + \frac{\psi_{i,j+1}}{a_j(a_j + a_{j+1})}\right]$$

FIGURE 17

Thoman and Szewczyk discuss the stability requirements for the explicit method in their report.

The difference approximation to a partial differential operator on a nonuniform mesh has a larger truncation error than that on a uniform mesh of similar cell size. The additional error arises due to the fact that the coefficient of the first neglected term in the Taylors series approximation to the derivative contains the difference of the mesh sizes on each side of the point of interest. When the mesh size is uniform, this difference is zero and the effective accuracy of the approximation is increased by one order. However, in the case of a nonuniform mesh, this term must be retained and it contributes to the error in the approximation.

The importance of the error conditions mentioned above can be minimized when taken over the whole mesh by keeping the cell sizes constant wherever possible. When moving from a region of one cell size to that of another, the amount of cell to cell variation should be limited to an amount such that the coefficient of the first neglected term is always nearly zero. In addition, if the regions of changing cell size can be placed in areas where the value of the first neglected derivative itself is expected to be small, the error encountered will be even smaller.

Another technique to reduce error has been proposed but was not used in this study. After applying the explicit form to compute the values at the next time step, use the finite difference forms of the neglected derivatives to evaluate the error caused by truncating the Taylors series approximation. Subtract this error from the computed values and repeat the process until the calculated truncation error is reduced to zero. This technique would improve the accuracy of the symmetric and asymmetric solutions and consideration should be given to applying it to these problems.

5.3 Programming the Algorithm

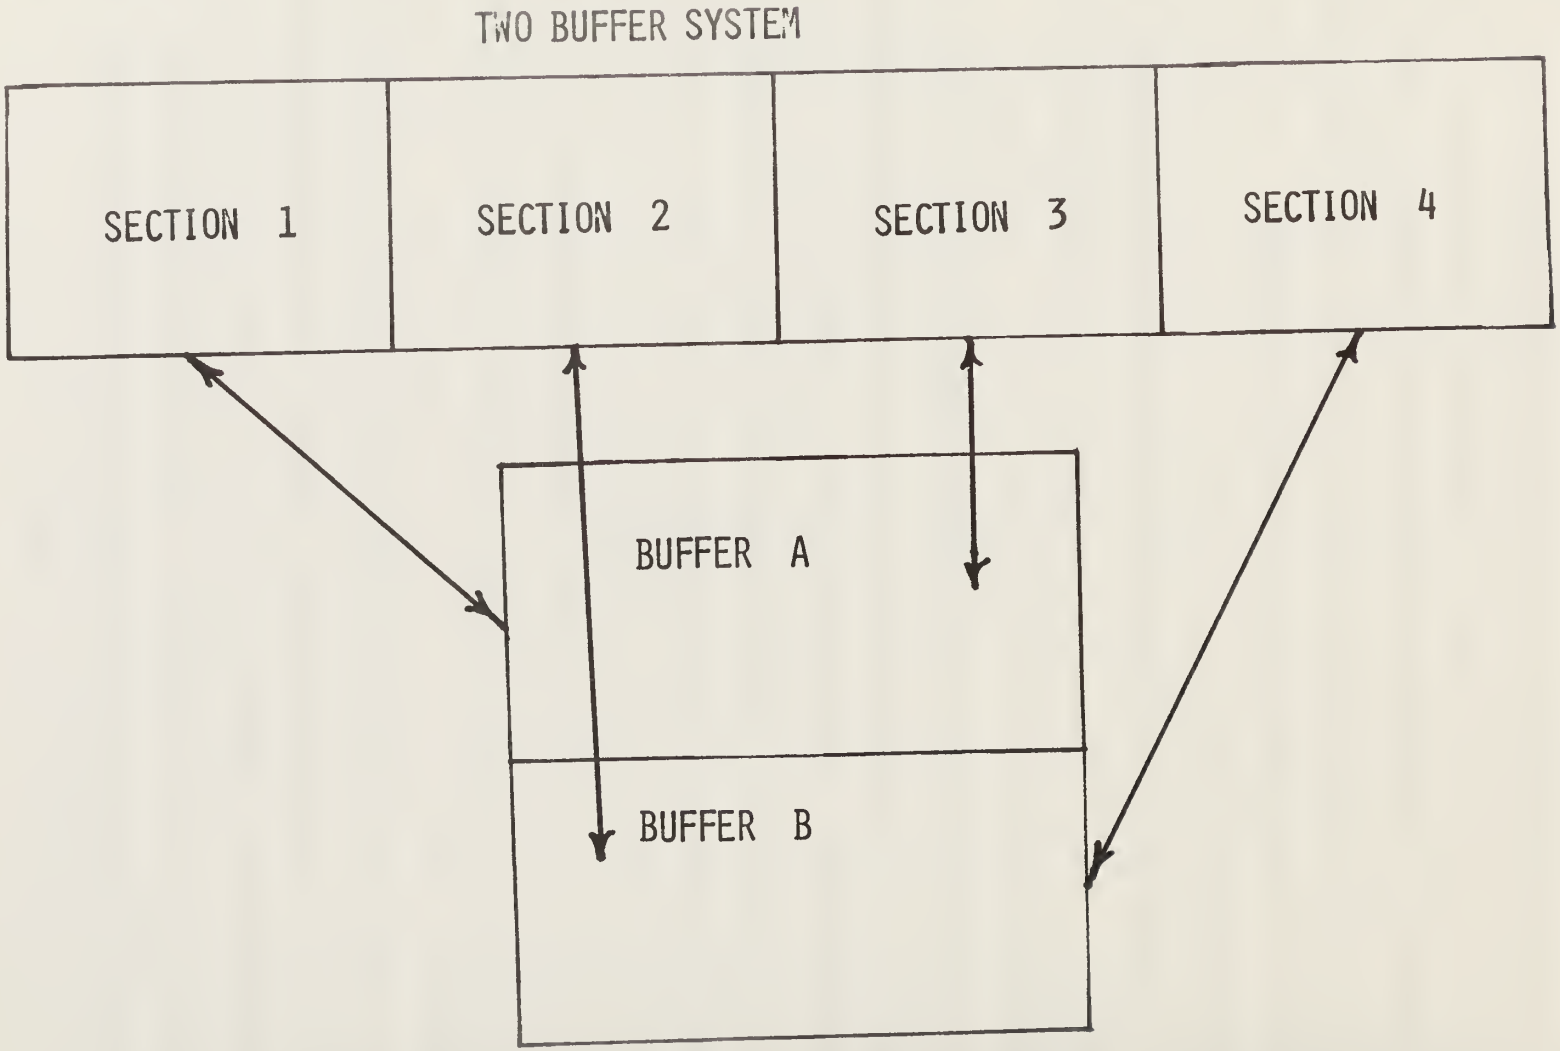
The program for the asymmetric flow problem is coded in the latest version of GLYPNIR. Appendix E contains the sections of code which have been completed at this time. Further work on the program will be needed before it can be run on ILLIAC IV. The following sections of the report discuss some of the problems encountered in programming this large code for ILLIAC, and describes some possible solutions. No attempt to optimize the code has been made at this point in its development.

5.3.1 The buffer system

The symmetric problem was small enough to be core contained. The asymmetric case, however, was too large to fit in the PEM and thus a buffer system was developed.

The total number of rows of PEM storage required to hold the entire stream function mesh was first determined. The total was then divided into four sections each containing nearly the same number of rows. This division was made strictly on the basis of the number of rows, without regard to the boundaries of the various flow regions. The section sizes were then doubled to account for the vorticity storage needed. A separate disk file was set up to hold each of the 4 sections. Two areas were reserved in the PEM, each area large enough to hold one section. The Buffer System is illustrated in Figure 18.

During the course of the computation, a section is read into or written out of one area while calculations proceed in the other. When calculations and transfers are complete, calculation moves to the second area and transfers begin on the area just calculated. Because of ILLIAC 's great speed, it is expected that the transfer times will exceed the calculation time in most problems, a condition known as being I/O bound.



TWO BUFFER SYSTEM
SECTION 1
SECTION 2
SECTION 3
SECTION 4
BUFFER A
BUFFER B

FIGURE 18

A working row (or rows) was designated outside of the transferable areas in PEM to assist in the transportation of information from one section to the next. When calculations are complete in a section, the last row in that section is moved to the work area. The first operation on the next section is to insert the new information from the work area into the first row. The calculations can then proceed as usual.

The sectioning of the program and the use of two buffers suggested that a separate piece of code could be used to carry out the calculations in each section. This idea has been implemented through the use of a separate subroutine for each section. The technique provides a logical organization to the program. It is particularly useful in this problem as it allows a fairly complicated program to be broken down into a series less complicated units.

5.3.2 Organization of PEM

The arrangement of the mesh points in PEM is a very important operation in setting up the program. It is necessary to lay out each buffer as a separate unit, indexed all the way through with respect to its first row. Figures 19 through 22 present the allocation of PEM storage for each buffer load. The numbers along the right edge are the buffer indicies. On their right are the coordinate value of the mesh line stored in that PEM row. The numbers on the left represent the regional indicies, indexed relative to the first row in the region. All of these indicies are used in the program.

The number of data points in a mesh row exceeds 64 in several regions. This makes necessary the sectioning of the row into pieces,

FIGURE 22

each of which will fit into a PE row. This sectioning results in complicated indexing problems. The sketches shown in Figures 19 to 22 are very useful in keeping the indexing straight. It is also necessary to leave at least one working position each side of the split in the row and to exchange data between working spaces as the computation proceeds from one PE row to another within a mesh row. This does cut into the efficiency of the calculations but it is difficult to assess how much.

The boolean mode variables control the enabling and disabling of PE's in the array. Each row has its own mode pattern. These patterns are carefully constructed so as to define exactly the active mesh. Separate mode patterns must be used when boundary conditions are evaluated. The data allocation sketches are very helpful in setting up the proper mode control patterns.

The nontransferable portion of PEM contains a number of variables which are associated with specific mesh points. The principle variables are the coordinate values of each mesh point, the cell width and height of each mesh point and the modes for each row. These are all assessed by regional indicies and are given a variable name which indicates to which region they belong. The coordinates and cell sizes must be provided by the user before the program is compiled. A separate procedure could be developed to obtain the cell sizes from the coordinates but that is not implemented in this program.

5.3.3 Boundary conditions

The boundary conditions which involve the endpoints of PEM rows require special attention. Each point must be treated separately, as in a serial machine. Since the endpoints are a small fraction of the total

mesh points, this inefficiency may not be too serious. The boundaries which involve whole PE rows are handled with little loss of efficiency.

The downstream boundary conditions used in this problem were taken directly from the report of Thoman and Szewczyk. They are that the axial velocity gradient and the axial vorticity gradient are both zero. These boundary conditions were selected from those experimentally tested as the ones which produced the most desirable solution. These conditions should be used in the initial version of this program but other more Physically realistic conditions should be examined in the future. A boundary layer type of outflow condition with $\frac{\partial^2 \zeta}{\partial x^2} = 0$ and $\frac{\partial^2 \psi}{\partial x^2} = 0$ might produce satisfactory results. The fact that the distance between their cylinder and the downstream boundary was only 8.5 diameters may be one reason why Thoman and Szewczyk had difficulty with other boundary conditions. The asymmetric program developed here extends to 50 diameters.

5.3.4 Changing regions

At the place where the mesh distribution across the rows changes, a special treatment of the data must take place. If more mesh points are added, an interpolation is required. This is the case in going from Region 2 to Region 3. It can be seen that the new points needed have been placed exactly halfway between the existing points so that a simple averaging can be used to obtain the new values.

The process is as follows. The last row in Region 2 is moved to a work array. A second work array is filled consecutively with values from the first array but every other position is left blank. From the values on each side of a blank an average is obtained and inserted in the blank space. This new work area is then moved to the first row in Region 3 and the calculations proceed as usual.

This method works even when simple averaging is not used. The appropriate number of blanks must be left in the new work area and interpolation on the bracketing values must then be carried out using the coordinate values of the points involved.

5.4 Current Status of Program

The overall computational scheme to be used in the solution of the asymmetric problem has been developed and can be seen in the structure of the procedures used in CICHY/UNS in Appendix E. Much of the detail discussed in the preceding sections has yet to be programmed. Keeping track of indicies and control modes represents a most difficult task but frequent reference to the allocation sketches has proved very helpful.

5.5 Conclusions

The asymmetric problem is an excellent test case for evaluating the use of ILLIAC IV in solving fluid dynamic problems. The features which make it most attractive are its large size, requiring the use of buffers and overlapping I/O, and its nonuniform mesh size, with the accompanying indexing problems. These features are held in common with many of the types of fluid dynamic problems invisioned for solution on ILLIAC IV. Thus if this problem can be solved efficiently and rapidly, there is great hope for the increased use of ILLIAC IV in numerical fluid dynamics.

The programming of a large problem such as this can be speeded by the use of storage allocation charts. These are particularly helpful in determining the correct indicies and enabling mode patterns.

The use of a buffer system to handle problems with large data sets appears to work well. Only when actual I/O times and processor times are available can the actual efficiency of this method be determined.

6. FUTURE PROGRAMS IN THIS PROJECT

There are several interesting studies which can be built on the present work. First, of course, the asymmetric program should be completed. This, along with the symmetric program, should then be run on ILLIAC IV and careful account made of the time actually needed to solve the problem. The resulting solutions should then be compared to the serial solutions previously obtained and some conclusions drawn as to the benefit in speed and accuracy realized from using ILLIAC IV.

The effect of the actual mesh point density and distribution could be carried out easily once the asymmetric program is completed. It would be interesting to determine how to construct a mesh with just enough points to resolve the fluid motion accurately.

The effect of several downstream boundary conditions on the numerical solution could also be evaluated using the asymmetric program. It would be particularly interesting to evaluate boundary layer type conditions, since they imply that any fluid motions beyond the downstream boundary will not feed back to affect the solution near the cylinder.

An entirely different numerical approach to the problem of flow around a cylinder might be tried. Recently finite element methods have emerged as possible ways to solve fluid flow problems. Adapting these techniques for use on ILLIAC IV could be a useful and rewarding endeavor.

13. ABSTRACT

The usefulness of ILLIAC IV in solving numerical fluid dynamics problems is studied by developing a parallel algorithm for the unsteady two dimensional flow of an incompressible fluid around a circular cylinder. Two cases are studied, the symmetric case, for which an operational GLYPNIR program is included, and the assymetric case, for which a partially completed GLYPNIR program is attached. The programming of a parallel algorithm for ILLIAC IV is more difficult than programming a comparable serial algorithm but this additional difficulty is compensated for by the greatly reduced computation time required to solve the problem.
